- Intrusion Detection Systems
- Optimal Sensor Placement
- Alarm Prioritization and Attack Response

- Analysis of vulnerabilities and building a complete map showing all possible paths of multi-step penetration into the network, organized as an attack graph, is known as Topological vulnerability analysis.
- Single vulnerability may not pose a threat but combination of vulnerabilities may allow attackers reach critical network assets.
- TVA considers dependencies among vulnerabilities and combines them in a real way as real attackers might do.

Adjacency Matrix Visualization

- Attack graph of n vertices can be represented by matrix of $n \times n$.
- Rows and columns of matrix can be placed in any order, but orderings that capture regularities are desired.
- Regularities include cluster of vertices that have a common edge.
- Adjacency matrix shows reachability within single step.
- Adjacency matrix raised to power of P gives number of p -step paths between vertices.

- Native Matrix multiplication can be improved by spectral decomposition of A into V and D .
- D contains eigen values as diagonal elements and V is matrix of eigen vectors. Now, Large powers of A can be computed by raising D to large powers.
- Transitive closure of A gives for each pair of vertices, whether attacker can reach one graph vertex to another over all possible number of steps.
- Reachability matrix contains minimum no. of steps required to reach one vertex from another.

- No widely accepted security metrics
- Every metric is qualitative rather than quantitative
- 3 factors that account to quantitative security metrics are
 - (i) *Significance of resource* - Prioritizes the resources
 - (ii) *Reconfiguration cost* - Provides the relative overhead for network hardening
 - (iii) *Attack Resistance* - Removes the idea of qualitative measure.

- It gives the likelihood of an attack
- For each exploit e and condition c we will be having individual probabilities $p(e)$, $p(c)$ and cumulative probabilities $P(e)$, $P(c)$.
- Individual probability is the likelihood of exploiting exploit e given all it's preconditions are satisfied.
- Cumulative probability represents the likelihood of reaching a state in which attacker can successfully exploit a given exploit.

Cummulative Probability

Fig. 2. Examples Showing the Need for Cumulative Scores of Conditions

- We follow 3 methods to avoid difficulties
 - a) Remove cycles.
 - b) Break edges
 - c) Neither remove cycles nor break edges

Attack Resistance

- Metrics are quantified based on the time and effort taken to compromise a given critical resource
- More the no.of attack paths the less secure is the network.
- Metrics are quantified by
 - (i) Assigning the real number values to attack resistances
 - (ii) Attack resistances are represented as set of initial conditions.

Real values assignment

- The attack resistance is quantified by a real number
- For an exploit e the attack resistance value is denoted by $r(e)$
- Cumulative attack resistance is similar to that of effective resistance in an electrical circuit
- Cumulative attack resistance is calculated using \oplus , \otimes between two resistances.
- $1/r1 \oplus r2 = 1/r1 + 1/r2$ - parallel condition
- $r1 \otimes r2 = r1 + r2$ - series condition
- $R'()$ function gives the modified attack resistance values when a particular exploit occurs.

Set of Initial Conditions

- Attack resistance is completely different from the previous approach
- Resistance here means set of initial conditions to be satisfied before an intrusion is possible.
- More the no.of initial conditions more the resistance

Network Hardening

- This is one of the first method to quantify the metrics
- Vulnerabilities should not be taken in isolation
- Every exploit is represented as a Boolean value and attack path is represented as a function of these Boolean values
- We start building a dependency graph with initial conditions as post conditions.
- In forward building of dependency graph we avoid redundancies by avoiding cycles.
- Once we reach the goal we do a backward processing in order to get those states that are not reachable from initial state but are relevant to the attack goal.
- This results in a set of minimal attack paths.
- $g = p + qr + qs$
 $= (p+q+r+s).(p+q+r+s').(p+q+r'+s).(p+q+r'+s').(p+q'+r+s)$

 - Intrusion Detection Systems
 - Optimal Sensor Placement
 - Alarm Prioritization and Attack Response

Correlating Intrusion Events

- Network vulnerability is ignored in most of the cases
- Joint model of attacker exploit and network vulnerability is created.
- Graph distance between the events is used to measure the correlation between the events.
- If an event is unreachable from previous one then it will be taken as a new event.

Correlating contd

- For easy calculations we take inverse of distance as it lies in the range of $[0,1]$
- We pass this distance function through an exponential weighted function in-order to take care of false alarms.
- This exponential weighted function is called low-pass-filter function.
- After passing through low-pass filter threshold value helps us to correlate the events.
- if d_k is the distance between events then consider

$$x_k = 1/d_k$$

$$\bar{x}_k = P.x_{k-1} + (1 - p)x_k \quad 0 \leq p \leq 1$$

\bar{x}_k represents the filtered version of original sequence

 - **Intrusion Detection Systems**
 - Optimal Sensor Placement
 - Alarm Prioritization and Attack Response

- Traditionally sensors are placed at network perimeters.
- Sensors report all malicious traffic without any regard to actual network configuration, vulnerabilities and mission impact.
- To reduce false alarms, attack graphs are built based upon network configuration, vulnerabilities and attacker exploits.
- Sensors are placed in minimal number to protect mission critical assets.

Sensor Placement

- Even though firewalls, routers ACLs are present still residual vulnerabilities are present.
- To minimize costs, Minimum no of sensors are placed to cover all critical paths. This is an instance of NP Hard Problem.
- Greedy algorithm for NP Hard Minimal set cover problem gives polynomial time solution.
- Algorithm is as follows
 - At every stage, select the set with large no. of elements.
 - If there are more sets with equal large no. of elements, select the one with more infrequent elements.

Optimal Sensor Placement

 - Alarm Prioritization and Attack Response

Alarms Prioritization and Attack Response

- Attack graphs are used to correlate IDS alarms, prioritize them and predict the future steps and respond accordingly.
- Attack origin and goal can be predicted from alarms and adjacency matrix.
- For an alarm, non-zero elements along the projected row show all possible single steps forward. Projection along column gives attack origin.
- Alarms are prioritized based on distance from critical networks assets. Closer to critical assets are given higher priority.
- If attack is detected, we can predict the next steps and block that particular machines and ports
